WMH and long-term outcomes in ischemic stroke

A systematic review and meta-analysis

Abstract

Objective

To investigate the relationship between baseline white matter hyperintensities (WMH) in patients with ischemic stroke and long-term risk of dementia, functional impairment, recurrent stroke, and mortality.

Methods

Following the Meta-analysis of Observational Studies in Epidemiology and Preferred Reporting Items for Systematic Reviews and Meta-Analyses guidelines (PROSPERO protocol: CRD42018092857), we systematically searched Medline and Scopus for cohort studies of ischemic stroke patients examining whether MRI- or CT-assessed WMH at baseline are associated with dementia, functional impairment, recurrent stroke, and mortality at 3 months or later poststroke. We extracted data and evaluated study quality with the Newcastle–Ottawa scale. We pooled relative risks (RR) for the presence and severity of WMH using random-effects models.

Results

We included 104 studies with 71,298 ischemic stroke patients. Moderate/severe WMH at baseline were associated with increased risk of dementia (RR 2.17, 95% confidence interval [CI] 1.72–2.73), cognitive impairment (RR 2.29, 95% CI 1.48–3.54), functional impairment (RR 2.21, 95% CI 1.83–2.67), any recurrent stroke (RR 1.65, 95% CI 1.36–2.01), recurrent ischemic stroke (RR 1.90, 95% CI 1.26–2.88), all-cause mortality (RR 1.72, 95% CI 1.47–2.01), and cardiovascular mortality (RR 2.02, 95% CI 1.44–2.83). The associations followed dose-response patterns for WMH severity and were consistent for both MRI- and CT-defined WMH. The results remained stable in sensitivity analyses adjusting for age, stroke severity, and cardiovascular risk factors, in analyses of studies scoring high in quality, and in analyses adjusted for publication bias.

Conclusions

Presence and severity of WMH are associated with substantially increased risk of dementia, functional impairment, stroke recurrence, and mortality after ischemic stroke. WMH may aid clinical prognostication and the planning of future clinical trials.

Glossary

CI = confidence interval; DSM = *Diagnostic and Statistical Manual of Mental Disorders*; FLAIR = fluid-attenuated inversion recovery; ICH = intracerebral hemorrhage; mRS = modified Rankin Scale; NIHSS = NIH Stroke Scale; OR = odds ratio; RCT = randomized controlled trial; RR = relative risk; WMH = white matter hyperintensities.

White matter lesions identified as areas of increased signal on T2-weighted and fluid-attenuated inversion recovery (FLAIR) MRI sequences or decreased signal on CT (for simplicity, termed white matter hyperintensities [WMH]) are the most common imaging feature of cerebral small vessel disease, a major health problem in aging societies.^{1–3} The prevalence of WMH increases substantially with age^{4,5} and with the presence of cardiovascular risk factors.^{6,7} In population-based cohort studies, WMH were independently associated with adverse outcomes including stroke,^{8,9} dementia,^{8,9} functional disability,¹⁰ and mortality.^{8,9}

WMH are even more common in patients with ischemic stroke than in the general population.^{11,12} Brain imaging is recommended in all patients with suspected stroke.¹³ Hence, precise knowledge of the prognostic role of WMH may have wide clinical implications. A growing number of studies suggest that WMH in ischemic stroke patients are independently associated with poor outcomes including dementia,^{14–16} functional disability,^{17–19} stroke recurrence,^{20–22} and death.^{23–25} However, the reported results vary between studies possibly because of small sample size in the majority of studies, variable methodology for the assessment of WMH, variable definitions of outcomes, and different follow-up intervals. Hence, the predictive role of WMH after ischemic stroke remains to be defined.

Here, leveraging data from published literature, we set out to explore the long-term prognostic significance of WMH in patients with ischemic stroke in a systematic review and meta-analysis. Specifically, we aimed to assess the association between WMH at the time of the index stroke with long-term risk of dementia, functional impairment, recurrent stroke, and mortality.

Methods

Standard protocol approvals, registrations, and patient consent

This systematic review was based on a predefined protocol (PROSPERO registration number: CRD42018092857) following the Meta-analysis of Observational Studies in Epidemiology (MOOSE) guidelines²⁶ and the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA).²⁷ As all analyses have been based on publicly available summary statistics and not individual-level data, no ethical approval from an institutional review board or informed patient consent were required.

Search strategy

We systematically searched Medline and Scopus from inception through June 1, 2018 (detailed search strategy in

e-Methods, doi.org/10.5061/dryad.8b62gn1), screened ProQuest and OpenGrey as sources of gray literature, and hand-searched the reference lists of eligible articles and relevant reviews without language or publication year restrictions. We evaluated studies for potential population overlap, based on geographical setting and recruitment period. In case of overlap, we included studies presenting the most fully adjusted model or the ones with the largest sample size. Two authors (M. Georgakis and M. Duering) performed the literature search independently, and differences were resolved through consensus.

Inclusion criteria

We considered eligible all prospective or retrospective cohort studies that included patients with ischemic stroke and examining the association of WMH at baseline with the outcomes of interest over a follow-up period of ≥ 3 months. Secondary analyses of randomized controlled trials (RCTs) examining the same outcomes were also included. Case-control studies, cross-sectional studies, case reports, case series of < 50 patients, and animal studies were excluded. Our target population was adult (≥ 18 years) patients with ischemic stroke. Studies examining exclusively patients with hemorrhagic stroke and patients with TIA were excluded. However, we included studies examining mixed populations of patients with ischemic stroke and TIA or hemorrhagic stroke, as ischemic stroke patients usually comprise the majority of participants in these cohorts.

In order to qualify for inclusion into the meta-analysis, WMH had to be assessed within the first 3 months after the index stroke event. We included studies assessing WMH by either MRI or CT, as previous studies have shown substantial agreement between the 2 methods.^{28,29} We further included both studies assessing WMH severity through semi-quantitative visual rating methods and studies with quantitative measurements of WMH volume.

Our primary outcomes included poststroke dementia, functional impairment, any recurrent stroke, and all-cause mortality, assessed over a period of ≥ 3 months after stroke. Dementia had to be defined by standardized criteria (e.g., DSM) or validated clinical rating scales (e.g., Clinical Dementia Rating scale). Cognitive impairment (mild cognitive impairment or dementia), defined by formal neuropsychological testing or global cognitive tests with validated cutoffs, was examined as a secondary outcome. Studies examining performance in specific cognitive domains in continuous scales were excluded. For functional outcome, we included studies using tools that have specifically been

validated to determine disability in the poststroke setting, such as modified Rankin Scale (mRS), the Oxford Handicap Scale,³⁰ the Barthel Index,³¹ and tools assessing functionality in activities of daily living.³² Functional impairment defined by a validated cutoff with any of these tools was our primary outcome, but we also separately examined poor functional outcome, defined by an mRS score of >2 or >1. Studies not dichotomizing functional outcome or not providing data allowing its dichotomization were excluded. For recurrent stroke, we considered studies assessing any recurrent stroke (ischemic or hemorrhagic) through imaging or clinical follow-up or through linkage with disease registries. Recurrent ischemic stroke was a secondary outcome. We included studies assessing all-cause mortality through assessment of death certificates, linkage with national death registry data, or via interview with informants during follow-up. Cardiovascular mortality including death due to ischemic heart disease or stroke was a secondary outcome.

Quality assessment

We evaluated study quality using the cohort subscale of the Newcastle–Ottawa scale.³³ The following criteria were assessed: representativeness of exposed cohort, selection of nonexposed cohort, exposure ascertainment, outcome presence at study onset, comparability of exposed and unexposed cohorts, outcome assessment, follow-up length, and follow-up adequacy. Quality score ranges from 0 to 9 points. Quality assessment is described in detail in the e-Methods (doi.org/10.5061/dryad.8b62gn1).

Data extraction

We used a predefined spreadsheet to extract the following information from each article: study characteristics (geographical setting, recruitment period, study design); population details (sample size, inclusion/exclusion criteria, stroke subtypes, age, sex, stroke severity, cardiovascular risk factors); WMH ascertainment (imaging modality, method and scale of quantification); outcome assessment (definition, follow-up timepoint, number of events); and statistical analysis (type of analysis, relative risk [RR], 95% confidence intervals [CIs], adjustments). If multiple analysis models were presented in the individual articles, we extracted the RRs from the most fully adjusted model. Studies examining cognitive outcomes, recurrent stroke, and mortality presented hazard ratios or rate ratios as effect estimates of RR, which were combined in the same meta-analyses, whereas studies examining functional outcome presented odds ratios (OR). When the effect estimate was not directly provided, we calculated RRs or ORs, respectively, through 2×2 tables. To address the time dependency of cognitive outcomes, recurrent stroke, and mortality, we also performed sensitivity analyses restricted to hazard ratios.

Statistical analysis

Our predefined primary analysis approach was a comparison of moderate/severe vs mild/none WMH, given the high prevalence of mild WMH alterations in imaging studies of

elderly individuals.⁴ To harmonize studies using different WMH rating scales for defining moderate/severe WMH, we used the definition suggested and validated for each individual scale. For studies assessing WMH volume and presenting results in quantiles, we set a cutoff above the median quantile to define moderate/severe WMH. When studies presented RRs for >1 WMH severity categories, we obtained the effect estimate for moderate/severe vs mild/none categories using the method suggested by Hamling et al.³⁴ We also performed alternative analyses comparing presence vs absence of WMH and continuous analyses for increasing WMH severity. Studies presenting continuous analyses on different severity scale ranges were harmonized to a 0–3 scale. Studies presenting continuous analyses for WMH volume were analyzed separately.

To account for the differences across studies regarding WMH assessment, we pooled the effect sizes of different studies using random-effects meta-analyses. We set our Bonferroni-corrected significance threshold to $p = 0.05/4 = 0.0125$ to correct for the 4 different primary outcomes. We evaluated between-study heterogeneity with the I^2 and the Cochran Q statistic; I^2 exceeding 50% or 75% was considered as moderate and high heterogeneity, respectively.³⁵ We evaluated publication bias using the Egger test (significance threshold set at $p < 0.10$),³⁶ and adjusted the pooled effect estimates for publication bias in a “trim and fill” analysis.³⁷

Sensitivity analyses were performed for the different imaging modalities (MRI/CT) and WMH quantification methods (semi-quantitative/volumetry). Additional subgroup analyses were conducted by study design (prospective/retrospective and after excluding RCTs), study population (solely ischemic stroke/ischemic stroke plus TIA or intracerebral hemorrhage [ICH]), degree of confounder adjustment (age, stroke severity, cardiovascular risk factors), stroke severity (NIH Stroke Scale [NIHSS] score), age (<70/≥70 years), WMH location (periventricular/deep), MRI sequence (FLAIR/T2), follow-up duration (<1/≥1 year), sum quality score, and fulfillment of every quality item. In case of heterogeneity, we examined whether it was explained by any of these factors. We further conducted meta-regression analysis to evaluate whether stroke subtypes, age, sex, education, NIHSS score, atrial fibrillation, hypertension, hypercholesterolemia, diabetes mellitus, smoking, stroke history, and coronary artery disease modified the examined associations.

For studies presenting WMH analyses in ≥3 levels of WMH severity and adjusting their results at least for age, we conducted dose–response meta-analyses for our primary outcomes. To assign “doses” to every WMH category, we harmonized every scale to a 0–3 severity scale (none, mild, moderate, severe).³⁸ We applied restricted cubic spline models, using generalized least square regression with predefined knots at 10th, 50th, and 90th percentiles, for individual studies and thereafter pooled the study-specific estimates using the restricted maximum likelihood method in

a random-effects meta-analysis.³⁹ All statistical analyses were conducted in Stata 13.1 (StataCorp, College Station, TX).

Data availability

The analysis for this study is based on published results from individual studies. Therefore, individual-level data cannot be made publicly available. All extracted data from the individual studies and the code used for performing the meta-analyses can be made available upon reasonable request to the corresponding author.

Results

Review of literature

Figure 1 illustrates the study selection process. The literature search yielded 6,562 articles that were screened for eligibility. Following evaluation of titles and abstracts, we examined the full text of 248 articles for eligibility. We excluded 128 articles that did not meet our eligibility criteria (table e-1, doi.org/10.5061/dryad.8b62gn1) and 16 articles because of overlap with other eligible articles (table e-2, doi.org/10.5061/dryad.8b62gn1), leaving 104 articles for inclusion into our systematic review. Thirty-one articles (n = 16,167 individuals) assessed cognitive outcomes, 49 articles (n = 25,559) assessed functional outcomes, 26 articles (n = 30,256) assessed recurrent stroke, and 28 articles (n = 15,533) assessed mortality.

Study characteristics

The characteristics of studies eventually included in the final analysis are presented in table e-3 (doi.org/10.5061/dryad.8b62gn1). Overall, the 104 studies included a total of 71,298 individuals (median sample size n = 266 individuals; minimum n = 56; maximum n = 9,522). Forty-four studies were retrospective cohort studies (n = 20,765), whereas 60 had a prospective design (n = 50,533). Of the latter, 3 studies presented results from secondary analyses of RCTs (n = 6,637). The majority of studies (101 out of 104 studies; n = 67,769) were hospital-based and examined older stroke patients (mean age ≥65 years in 82 studies; n = 62,304). Thirty-eight studies (n = 33,067) included TIA or ICH patients in addition to ischemic stroke patients, whereas 33 studies (n = 6,278) focused on specific ischemic stroke subgroups, mainly lacunar stroke or mild stroke. WMH were assessed solely through MRI in 66 studies (n = 47,963), solely through CT in 31 studies (n = 17,144), and through either method in 7 studies (n = 6,191). Regarding WMH quantification, 10 studies (n = 7,027) used volumetry, whereas 77 studies (n = 56,017) rated WMH severity with visual semi-quantitative rating scales, the most common of which were the Fazekas scale (40 studies; n = 39,776), the Van Swieten scale (15 studies; n = 6,977), and the age-related white matter changes (ARWMC) scale (15 studies; n = 8,248). The remaining 17 studies (n = 8,254) assessed WMH presence only through subjective visual assessment. Follow-up ranged from 3 months to 15 years with mean intervals of 38.3 months for cognitive outcomes, 5.8 months for

functional outcomes, 34.3 months for recurrent stroke, and 33.1 months for mortality.

Study quality

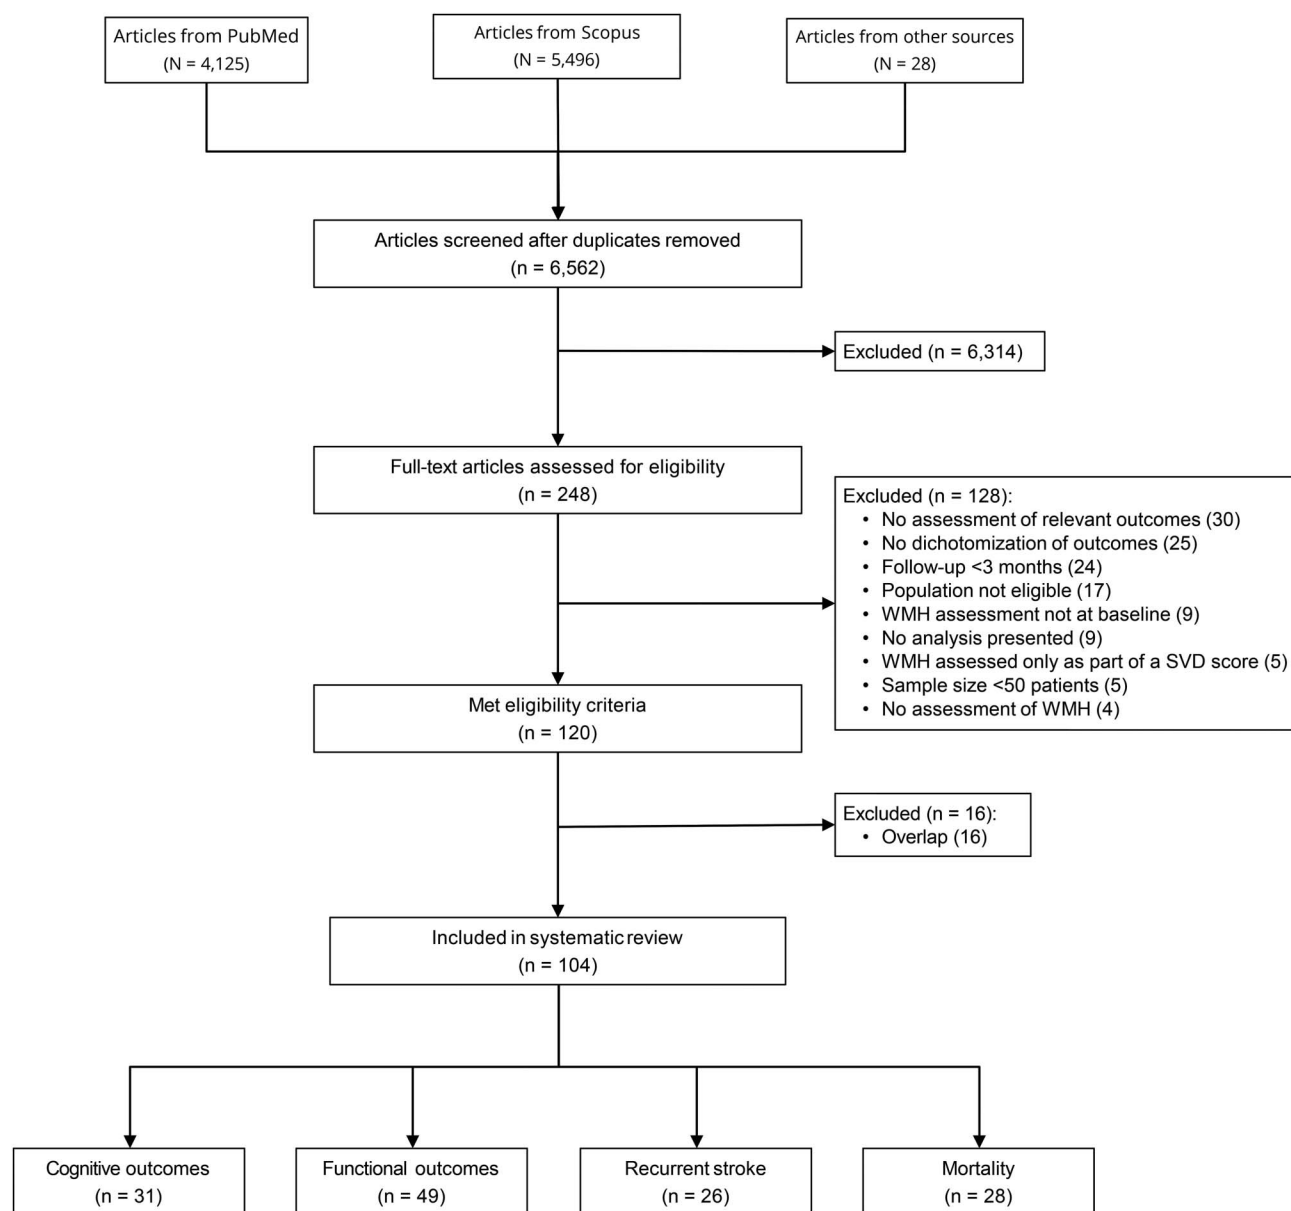

The overall study quality was moderate, with only 7 studies (7%) fulfilling all quality items assessed by the Newcastle–Ottawa scale (table e-4, doi.org/10.5061/dryad.8b62gn1). Median total quality scores for cognitive outcomes, functional outcomes, recurrent stroke, and mortality were 5/9, 7/9, 7/9, and 5/8, respectively. Regarding the items on selection bias, 33 studies (32%) lost quality points in representativeness of the cohort, 17 studies (16%) because of nonvalidated subjective assessment of WMH, and 57 studies (55%) for not ensuring absence of the outcome at study onset. Furthermore, 38 studies (37%) did not adjust their results for age and 41 studies (39%) did not adjust for cardiovascular risk factors or stroke severity. Regarding outcome assessment, 16 studies (52%) did not define dementia or cognitive impairment by standardized clinical criteria and formal neuropsychological assessment, 10 studies (38%) did not confirm recurrent stroke with imaging, and 16 studies (57%) examining mortality did not cross-link deaths with death certificates. Follow-up interval was considered short (<12 months) for 18 studies (58%) on cognitive outcome, 6 studies (23%) on recurrent stroke, and 10 studies (36%) on mortality. Finally, 61 studies (59%) did not meet the quality criteria for follow-up adequacy, as the attrition rates were >10%.

WMH and outcomes after stroke

We found moderate/severe WMH at baseline (figure 2A) to be associated with increased risk of dementia (RR 2.17, 95% CI 1.72–2.73; 12 studies; 12,341 individuals; 2,159 events), any functional impairment (RR 2.21, 95% CI 1.83–2.67; 25 studies; 16,339 individuals; 6,663 events), any recurrent stroke (RR 1.65, 95% CI 1.36–2.01; 14 studies; 24,166 individuals; 3,168 events), and all-cause mortality (RR 1.72, 95% CI 1.47–2.01; 15 studies; 11,553 individuals; 1,801 events) after ischemic stroke. Our analyses further showed that WMH were associated with all of the examined secondary outcomes including cognitive impairment (RR 2.29, 95% CI 1.48–3.54; 8 studies; 9,505 individuals; 1,299 events), mRS >1 (RR 1.96, 95% CI 1.67–2.29; 14 studies; 14,155 individuals; 7,350 events), mRS >2 (RR 2.27, 95% CI 1.84–2.81; 19 studies; 13,979 individuals; 5,899 events), recurrent ischemic stroke (RR 1.90, 95% CI 1.26–2.88; 6 studies; 5,505 individuals; 423 events), and cardiovascular mortality (RR 2.02, 95% CI 1.44–2.83; 5 studies; 2,499 individuals; 621 events).

The analyses examining WMH presence vs absence (figure 2B) and WMH severity in continuous analyses (figure 2C) likewise showed consistent results for all of the examined primary and secondary outcomes, except for cardiovascular mortality, where no studies were available for pooling. Forest plots of the above results are presented in figures e-1–e-4 (doi.org/10.5061/dryad.8b62gn1). A meta-analysis of studies examining WMH volume in linear association with any functional impairment had similar results (OR per 10 mL increase: 1.29, 95%

Figure 1 Flowchart on the selection of eligible articles

SVD = small vessel disease; WMH = white matter hyperintensities.

CI 1.10–1.51 and OR per 1 log-WMH volume: 1.20, 95% CI 1.01–1.44) (figure e-5, doi.org/10.5061/dryad.8b62gn1).

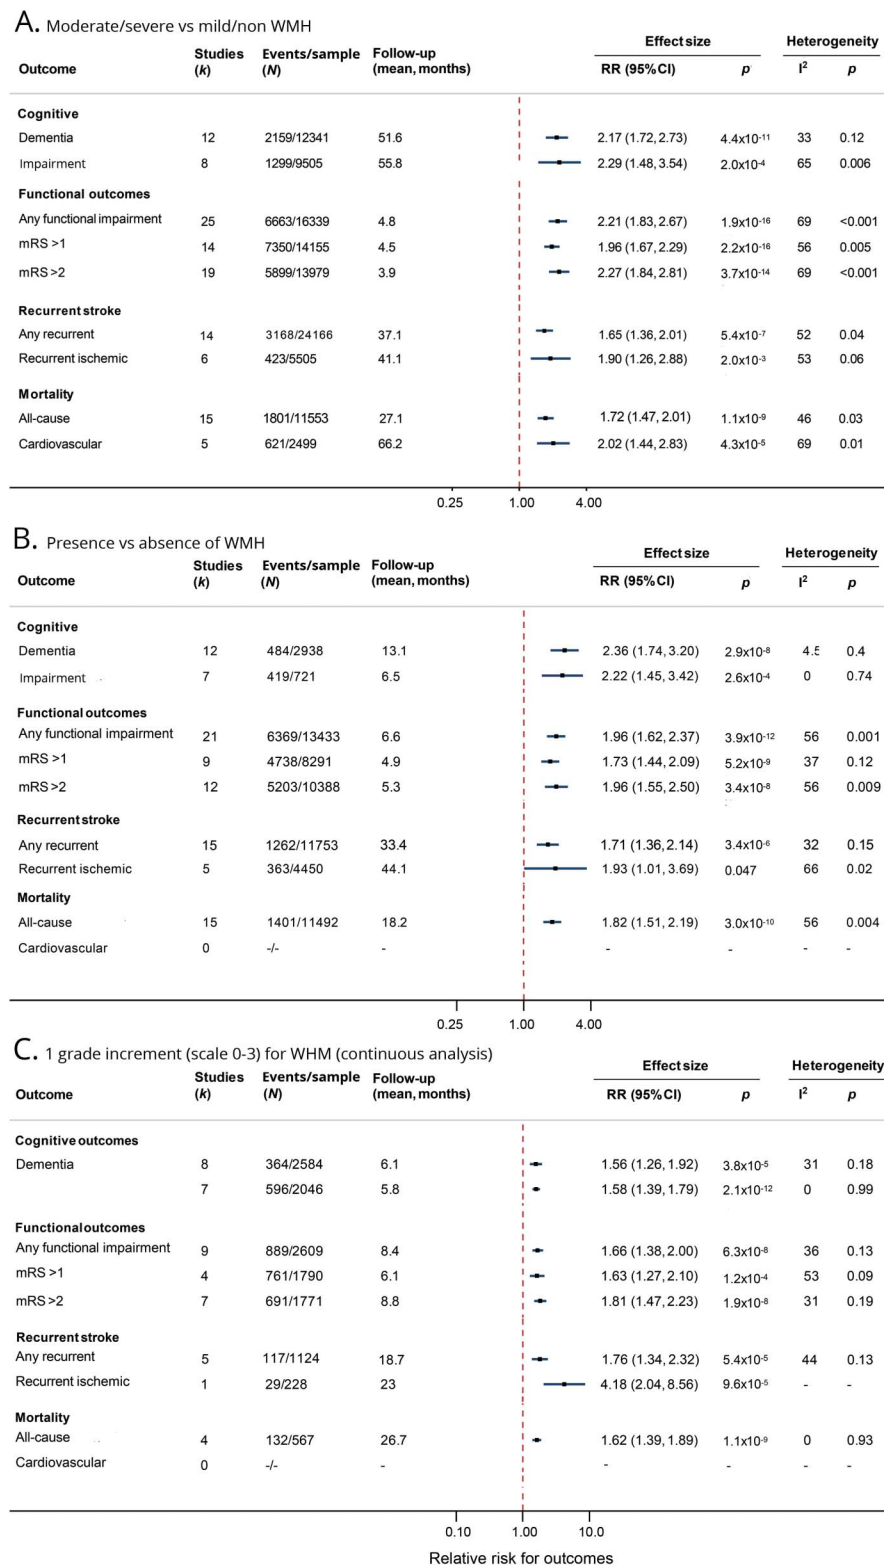

Heterogeneity and sensitivity analyses

We found moderate to high heterogeneity in the moderate/severe vs mild/none and in the presence vs absence analyses, but no heterogeneity was noted in the continuous WMH severity analyses (figure 2). To examine the sources of heterogeneity, we performed sensitivity analyses. Our results remained stable in sensitivity analyses restricted to studies of prospective or retrospective design, studies including solely patients with ischemic stroke, studies adjusting for age, stroke severity, or cardiovascular risk factors, studies of mean follow-up duration <1 or ≥1 year, studies of higher quality,

studies including patients <70 or ≥70 years and of different stroke severity, studies evaluating WMH by either MRI or CT, and in T2 or FLAIR sequences, studies quantifying WMH by volumetry or semi-quantitative scales, and studies examining periventricular or deep WMH (figure 3). Our results further remained stable in sensitivity analyses excluding studies based on secondary analyses of RCTs (figure e-6, doi.org/10.5061/dryad.8b62gn1) and when restricting the analyses to studies presenting hazard ratios as risk estimates (figure e-7, doi.org/10.5061/dryad.8b62gn1).

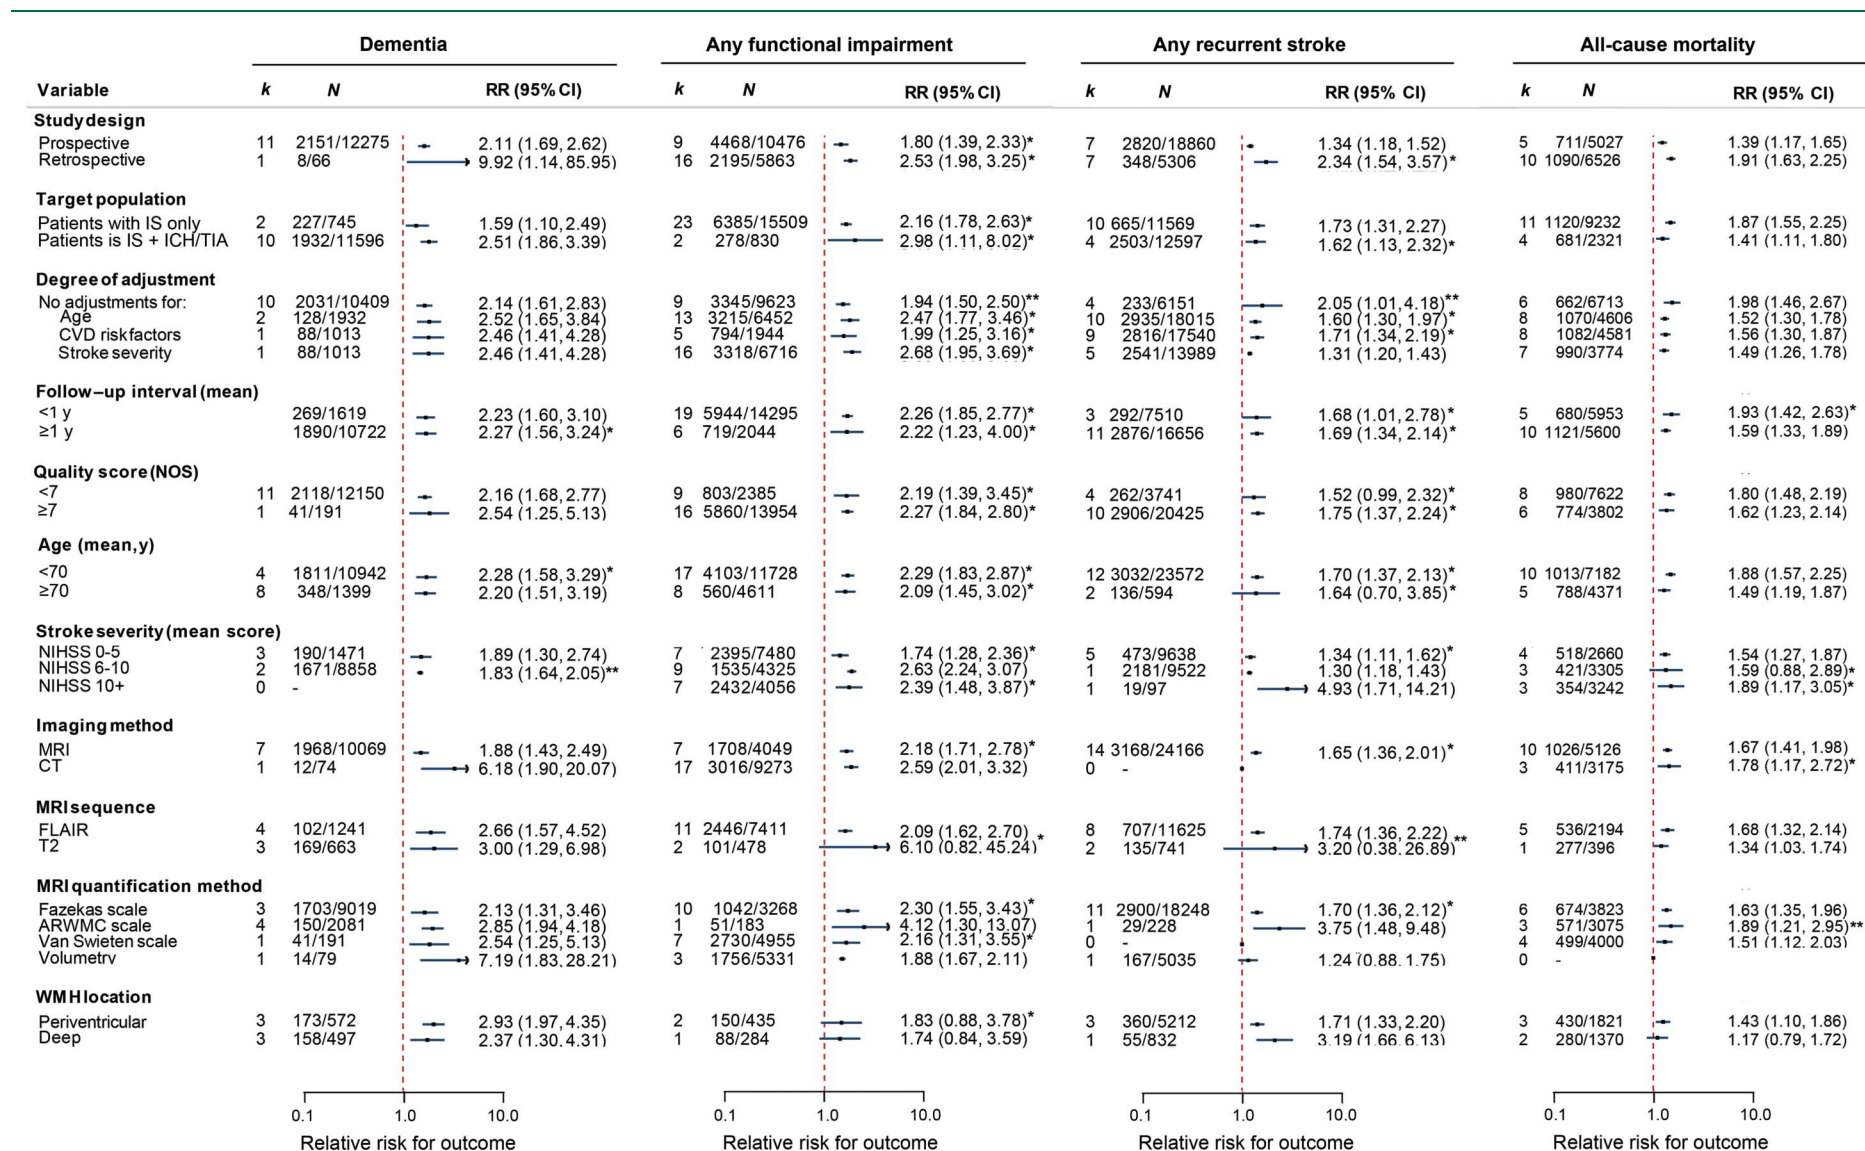

Interestingly, sensitivity analyses restricted to studies assessing WMH through FLAIR MRI were not accompanied by heterogeneity for any of the examined outcomes. Also,

Figure 2 Associations between white matter hyperintensities (WMH) at baseline and outcomes after stroke

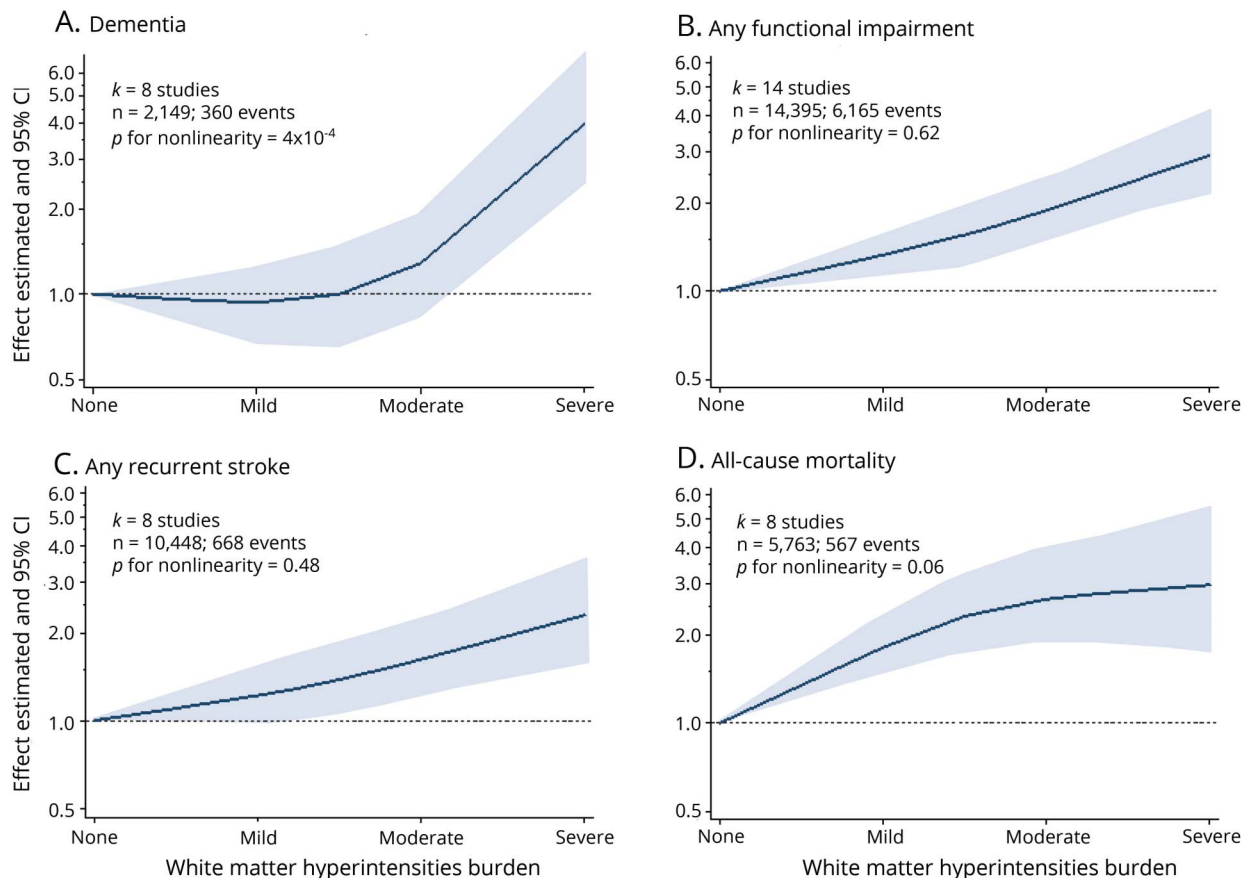

heterogeneity for dementia, any recurrent stroke, and all-cause mortality was resolved in analyses restricted to prospective studies, studies restricted to ischemic stroke patients, and studies adjusting for the maximum number of

confounders. Finally, no heterogeneity was noted for mortality when restricting analyses to studies with a follow-up ≥1 year (figure 3). Sensitivity analyses restricted to studies fulfilling every Newcastle–Ottawa scale quality criterion also

Figure 3 Subgroup analyses of the association of white matter hyperintensities (WMH) at baseline with stroke outcomes across different study characteristics

The forest plot depicts the summary effect estimates for the associations of WMH, examined as moderate/severe vs mild/none, with dementia, any functional impairment, any recurrent stroke, and all-cause mortality, by characteristics of the stroke population, neuroimaging methods, and quality factors of the included studies. ARWMC = age-related white matter changes; CI = confidence interval; CVD = cardiovascular disease; FLAIR = fluid-attenuated inversion recovery; ICH = intracerebral hemorrhage; IS = ischemic stroke; NIHSS = NIH Stroke Scale; NOS = Newcastle-Ottawa scale; RR = relative risk.

Figure 4 Dose-response meta-analysis of the age-adjusted association of white matter hyperintensities severity at baseline with stroke outcomes

The graphs depict the restricted cubic spline derived effect estimates and their 95% confidence intervals (CIs) for (A) dementia, (B) any functional impairment, (C) any recurrent stroke, and (D) all-cause mortality.

showed consistent associations of WMH with all of the outcomes (table e-5, doi.org/10.5061/dryad.8b62gn1). Importantly, we found no heterogeneity in analyses for dementia and recurrent stroke restricted to representative stroke populations, and to studies ensuring the absence of prestroke cognitive impairment or history of stroke at study onset, respectively (table e-5, doi.org/10.5061/dryad.8b62gn1).

Meta-regression analyses showed that none of the examined study population characteristics or quality score modified the associations of WMH with stroke outcomes (table e-6, doi.org/10.5061/dryad.8b62gn1). However, there was some indication that the effect size of the association between WMH and dementia increased with an increasing proportion of small vessel stroke and decreased with an increasing proportion of cardioembolic stroke within the study population.

Dose-response associations between WMH and outcomes after stroke

We next examined dose-response associations of WMH severity with stroke outcomes (figure 4). In age-adjusted

dose-response meta-analyses, we found linear associations between WMH severity and the relative risk for functional impairment (p for nonlinearity = 0.62; 14 studies; 14,395 individuals; 6,165 events), recurrent stroke (p for nonlinearity = 0.48; 8 studies; 10,448 individuals; 668 events), and all-cause mortality (p for nonlinearity = 0.06; 8 studies; 5,763 individuals; 567 events), but a nonlinear association for dementia (p for nonlinearity = 4×10^{-4} ; 8 studies; 2,149 individuals; 360 events). More specifically, WMH increased the risk for dementia only above a moderate WMH severity. Restricting analyses to studies further adjusting for stroke severity and cardiovascular risk factors yielded similar results (figure e-8, doi.org/10.5061/dryad.8b62gn1).

Assessment of publication bias

The Egger test supported presence of small-study effects indicating publication bias in several of the primary analyses (table e-7 and figure e-9, doi.org/10.5061/dryad.8b62gn1). Hence, we adjusted our results for publication bias through a “trim and fill” analysis. Importantly, the effect estimates were attenuated, but the associations remained in these adjusted analyses (table e-7, doi.org/10.5061/dryad.8b62gn1).

Discussion

Pooling data from 104 studies including >70,000 ischemic stroke patients, we found that WMH at the time of stroke are associated with multiple unfavorable long-term outcomes. Specifically, we found both the presence and an increasing severity of WMH to be associated with a higher risk of cognitive impairment and dementia, functional impairment, recurrent stroke, all-cause mortality, and cardiovascular mortality in follow-up intervals extending up to 15 years after stroke. The associations followed a dose-response pattern, with severe WMH being associated with the highest risk for poor long-term outcomes after stroke. The results were consistent regardless of imaging modality, were stable in sensitivity analyses of studies scoring high in quality and of studies adjusting for age, stroke severity, and cardiovascular risk factors, and remained after adjustment for publication bias.

Our findings extend previous literature on the prognostic role of WMH in the general population.^{8,9} Stroke marks a high-risk population amenable to preventive therapies and regular monitoring. Other than healthy elderly, almost all stroke patients receive brain imaging as part of their diagnostic workup.¹³ WMH can be reliably assessed on routine CT and MRI scans.^{28,29,40} As such, our finding of a predictive role of WMH for multiple long-term outcomes might have wide clinical implications. Specifically, the assessment of WMH might aid clinical prognostication, contribute to the interpretation of clinical trials, and possibly also influence treatment decisions, although this would need to be examined in controlled trials. To date, there are no treatment options with proven efficacy for slowing or halting the progression of WMH lesions. In any case, as WMH influence stroke outcomes, they should (1) be considered as a confounder for inclusion in minimization algorithms to balance baseline characteristics during randomization into trials; (2) be examined for potential interactions with treatment effect; and (3) be explored as a prognostic variable in future observational studies of patients with ischemic stroke.

The mechanisms underlying the associations of WMH with stroke outcomes are poorly understood. Potential explanations come from the following observations: first, WMH severity has been associated with infarct growth and larger infarct volumes in ischemic stroke patients,^{41–43} suggesting that the pathologic changes underlying WMH enhance susceptibility to acute ischemia. Indeed, WMH have been associated with both microvascular rarefaction⁴⁴ and reduced blood flow⁴⁵ not only in WMH, but also in normal-appearing brain tissue. Second, similar to other manifestations of small vessel disease,⁴⁶ WMH are a risk factor for symptomatic intracerebral hemorrhage after ischemic stroke in patients receiving thrombolysis.^{19,47} Third, we found that WMH increase the risk for stroke recurrence long-term, which might in part explain the association between WMH and cognitive outcome, functional outcome, and mortality. Of note,

however, the stroke recurrence rate observed here was lower than the incidence rates for these events. Hence, the effects of WMH on risk of dementia, functional impairment, and mortality are not sufficiently explained by the effects on stroke recurrence. Fourth, WMH might influence poststroke outcomes by disrupting neuronal networks relevant for cognitive reserve⁴⁸ and rehabilitation.⁴⁹ Finally, WMH might reflect the systemic burden of vascular risk factors known to influence stroke outcome,^{6,7} although the results remained stable in studies adjusting for these factors.

The identified interaction between ischemic stroke subtype and the effect of WMH on dementia risk perhaps reflects fundamental differences in mechanisms of dementia after different ischemic stroke subtypes. Specifically, we found the association between WMH burden and poststroke dementia to be stronger in studies with higher representation of small vessel stroke. This interaction could relate to aspects of infarct location involving strategic lesions in subcortical gray or white matter.⁵⁰ Nevertheless, these findings are difficult to interpret in a meta-analysis setting and future original observational studies are needed to clarify the role of ischemic stroke subtypes in the examined associations.

This study has several strengths. Our systematic review was based on a predefined protocol and followed standard guidelines with rigorous screening of >6,000 articles including sources of gray literature and without language or publication year restrictions. Our pooled analysis was based on a large number of studies examining a wide range of stroke outcomes in more than 70,000 patients, thus providing robust estimates for the associations of WMH with dementia, functional impairment, mortality, and recurrent stroke. Finally, extensive sensitivity and meta-regression analyses enabled us to control for confounding and other forms of bias.

Our study also has limitations. First, the main analyses revealed substantial heterogeneity. Potential sources of this heterogeneity include between-study differences in target population, study design, assessment and quantification of WMH, definition and ascertainment of outcomes, follow-up duration, and statistical approaches. Second, the majority of studies were of rather lower quality. Specifically, several of the included studies were not representative of the general stroke population, showed high attrition rates, did not assess whether outcomes were present before stroke, and did not adjust for major confounders such as age, NIHSS, and cardiovascular risk factors. Third, our analyses suggest marked publication bias for all outcomes investigated. However, the associations between WMH and long-term outcomes remained when adjusting for publication bias. Finally, we could not examine the influence of the index infarct on the technical assessment of WMH and whether this affected the results.

This meta-analysis shows that in patients with ischemic stroke, both the presence and extent of WMH are associated

with substantially increased risk of multiple long-term outcomes including dementia, functional impairment, recurrent stroke, and mortality. Our findings may have implications for clinical prognostication and the planning and interpretation of clinical trials.

Study funding

Vascular Dementia Research Foundation; Deutsche Forschungsgemeinschaft (German Research Foundation); Munich Cluster for Systems Neurology (EXC 1010 SyNergy); European Union’s Horizon 2020 research and innovation programmes under grant agreements 666,881 (SVDs@target) and 667,375 (CoSTREAM); German Center for Neurodegenerative Diseases (DZNE). The funding organizations had no role in the design or conduct of the study; collection, management, analysis, or interpretation of the data; preparation, review, or approval of the manuscript; or decision to submit the manuscript for publication.

Disclosure

The authors report no disclosures relevant to the manuscript. Go to [Neurology.org/N](https://www.neurology.org/N) for full disclosures.

Publication history

Received by *Neurology* August 8, 2018. Accepted in final form November 13, 2018.

Appendix 1 Authors

Name	Location	Role	Contribution
Marios K. Georgakis, MD	LMU Munich, Germany	Author	Concept and design; data acquisition, analysis, and interpretation of data; statistical analysis; drafting of the manuscript; critical revision of the manuscript for intellectual content
Marco Duering, MD	LMU Munich, Germany	Author	Data acquisition, analysis, and interpretation of data; critical revision of the manuscript for intellectual content
Joanna M. Wardlaw, MD	University of Edinburgh, UK	Author	Data acquisition, analysis, and interpretation of data; critical revision of the manuscript for intellectual content
Martin Dichgans, MD	LMU Munich, Germany	Author	Concept and design; data acquisition, analysis, and interpretation of data; drafting of the manuscript; critical revision of the manuscript for intellectual content
